

# Neutron reco in ECAL with TOF

Chris Marshall

Lawrence Berkeley National Laboratory

18 March, 2019

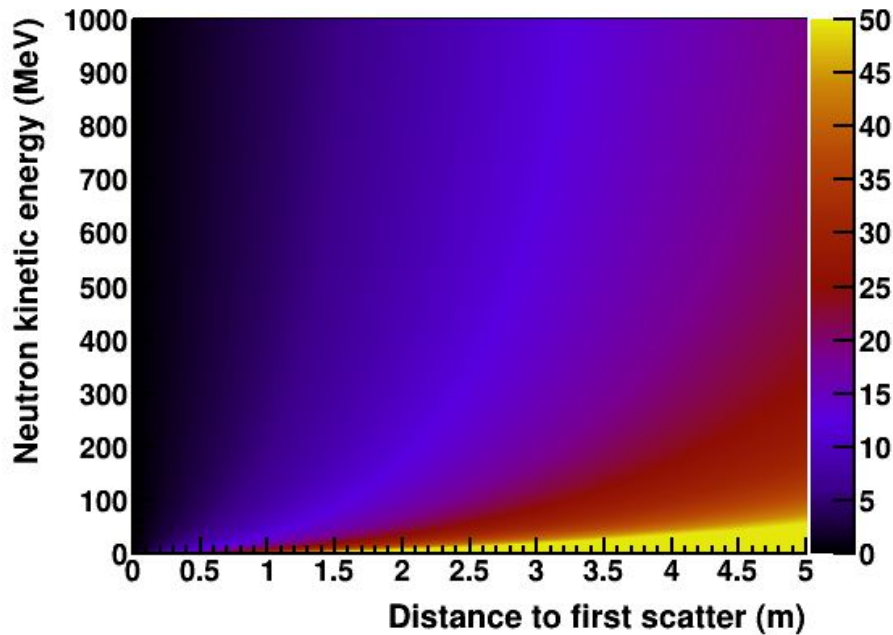

# Motivation

- Neutron production by (anti)neutrinos is highly uncertain, and is a large source of neutrino energy misreconstruction
- Measuring neutron energy with TOF has been demonstrated by MINERvA, and demonstrated for DUNE by 3DST group
- Similar technique using ECAL is promising
  - Measure neutron production on Ar directly
  - Long lever arm → improved energy resolution
  - Combine HPG TPC charged particle resolution with neutron reconstruction for excellent measurement of  $E_\nu$

# Time of flight vs. energy and energy resolution

Time of flight (ns)

Neutron fractional energy resolution

- Left: neutron time of flight as a function of lever arm, and kinetic energy
- Right: Fractional energy resolution for  $\sigma(\text{time}) = 0.7$  ns on both vertex and endpoint timing, assuming you can identify the first neutron interaction (pen and paper calculation)

# Recoil proton kinetic energy

Neutron KE = 150 MeV

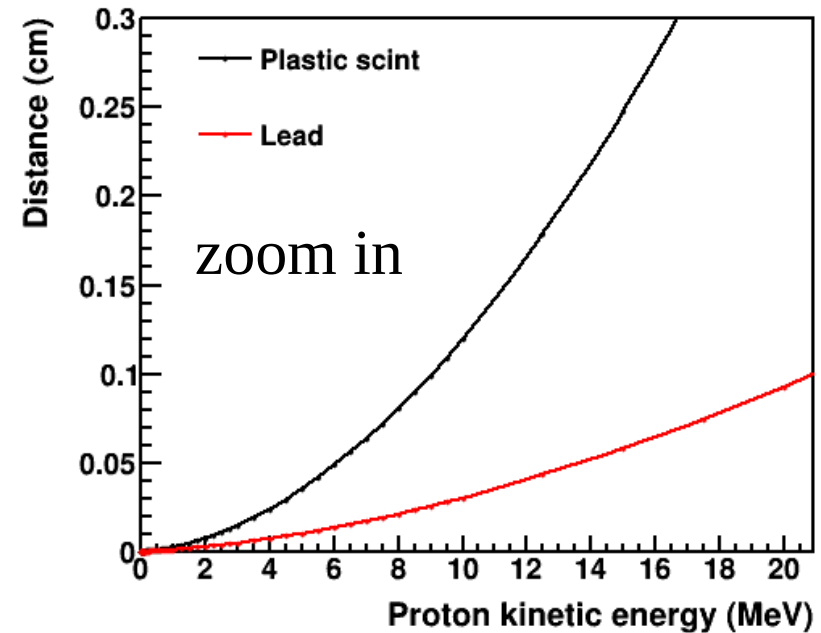

Neutron KE = 500 MeV

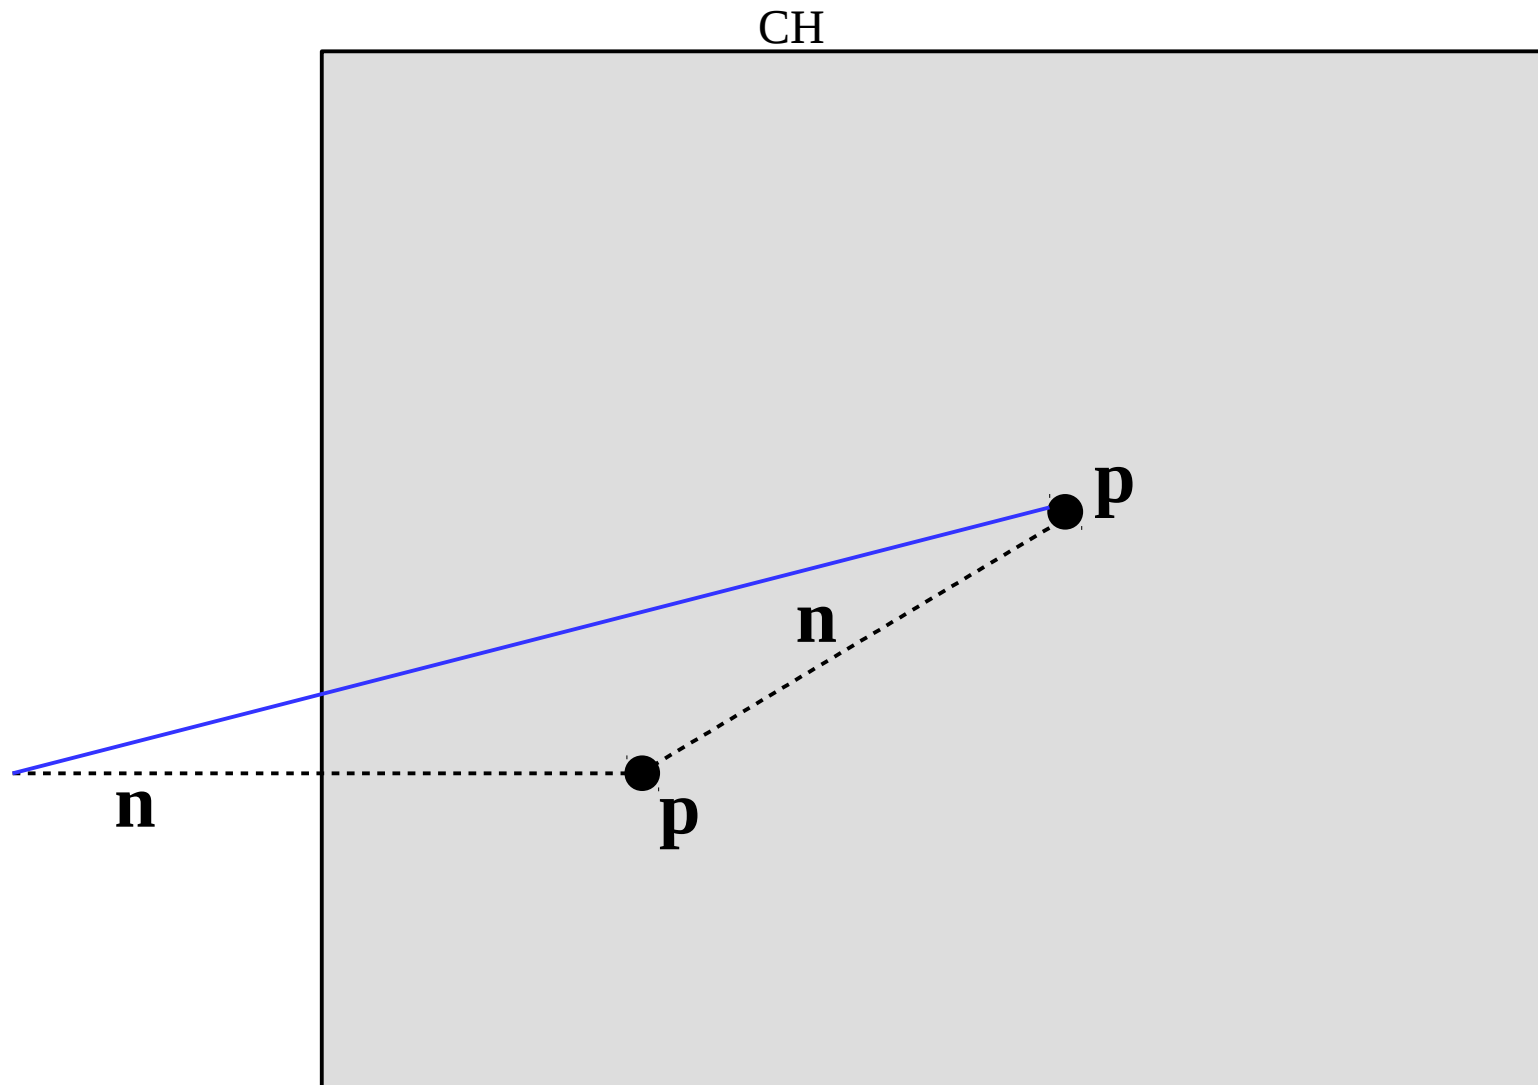

- Most recoil protons are  $\sim 3$ -10 MeV kinetic energy, independent of the energy of the incoming neutron
- Detector must be sensitive to isolated, few-MeV energy “blip”

# Proton stopping distance

- 10 MeV proton goes  $\sim 1\text{mm}$  in plastic,  $\sim 300\mu\text{m}$  in lead
- Protons will not traverse multiple detector layers unless they are sub-mm thickness, so need fully 3D readout

# Misreconstruction of energy

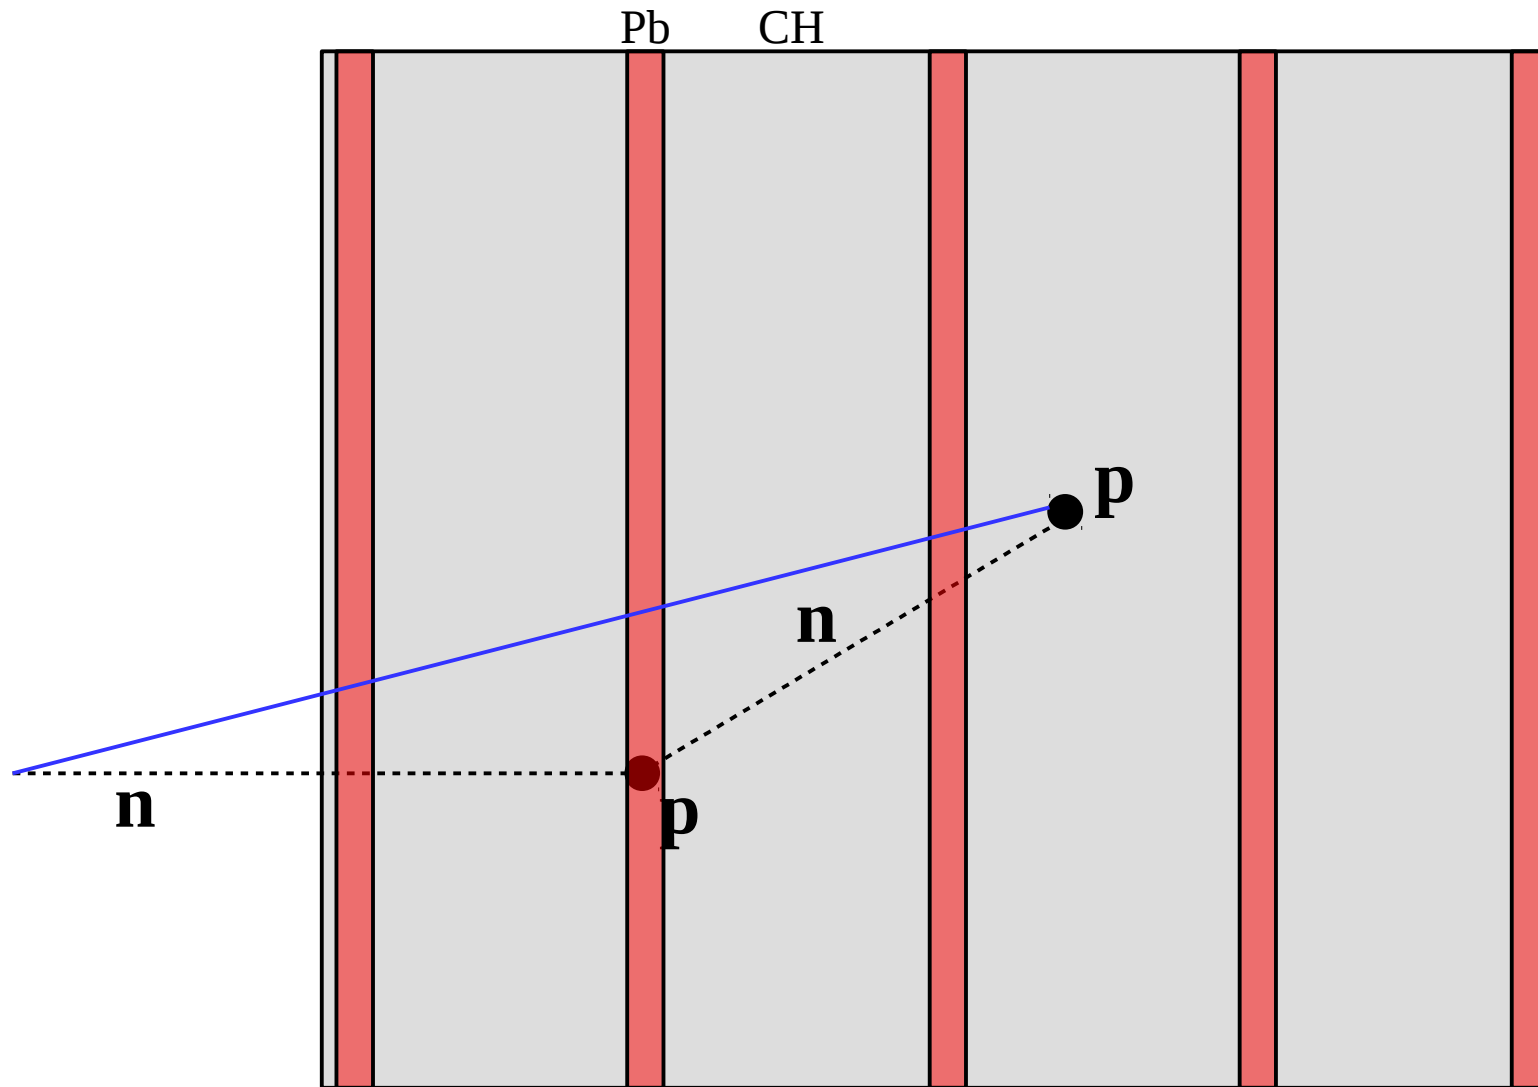

Miss first interaction → underestimate distance traveled

Second neutron is slower → TOF gives overestimate of initial neutron's energy

$\beta = d/t \rightarrow$  underestimate energy

# Unique challenge for ECAL

“Missed scatters” are more common because of passive absorbers

Expect low-side tails to be larger for ECAL than fully-active detector like 3DST

# Optimizing ECAL parameters

- Want to minimize interactions in absorber compared to active scintillator → high-Z, short- $X_0$  material → lead
- Density is  $\sim 10x$  higher than scintillator, so to get  $\sim$ equal interaction rate in CH and PB, need  $\sim 10x$  thicker scintillator
- We use 2mm Pb + 20mm CH to study resolution and efficiency:
  - Single neutron gun
  - Assume 0.7ns uncertainty on vertex and neutron recoil
  - Require 5 MeV true proton energy deposit (adding scintillator quenching in progress...)
  - Separate events based on “first scatter” or otherwise

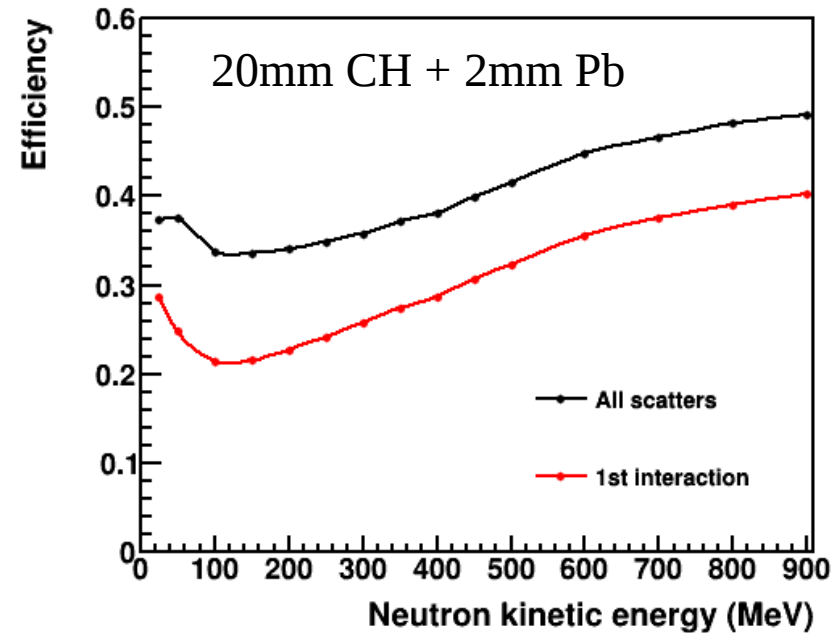

# Efficiency vs energy

20 modules

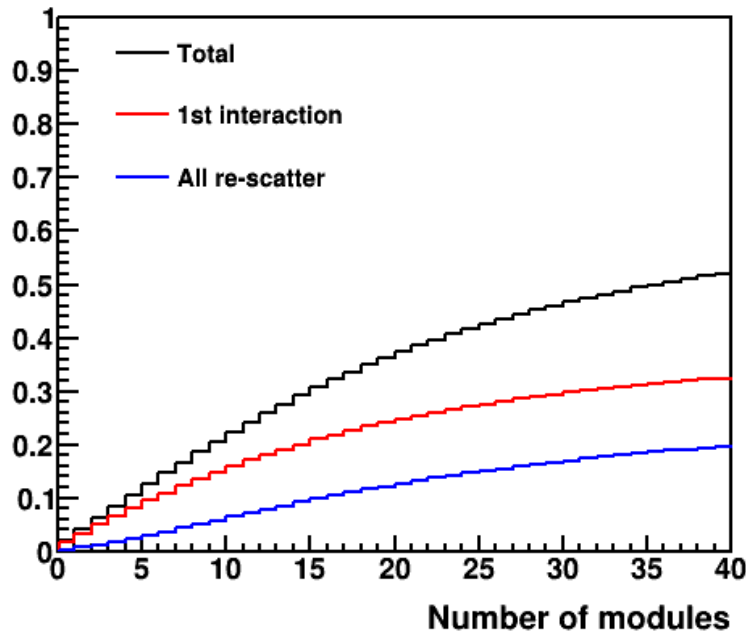

20 modules

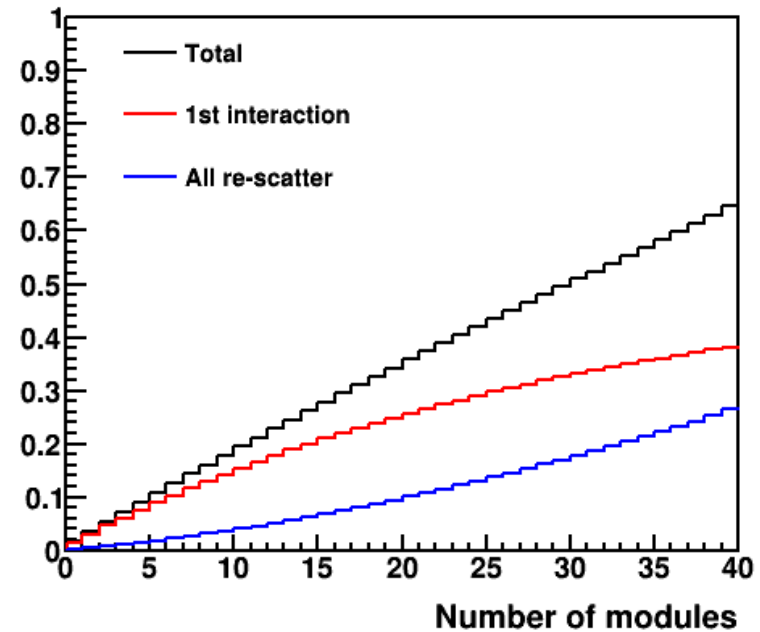

- Efficiency for  $\sim 8 X_0$  ECal in two configurations
- Left: thin 5mm CH tiles
- Right: thick 2cm CH tiles  $\rightarrow$  efficiency increases from  $\sim 25\%$  to  $\sim 40\%$ , almost entire increase is “first interaction”

# Efficiency vs ECAL thickness

Neutron KE = 50 MeV

Neutron KE = 300 MeV

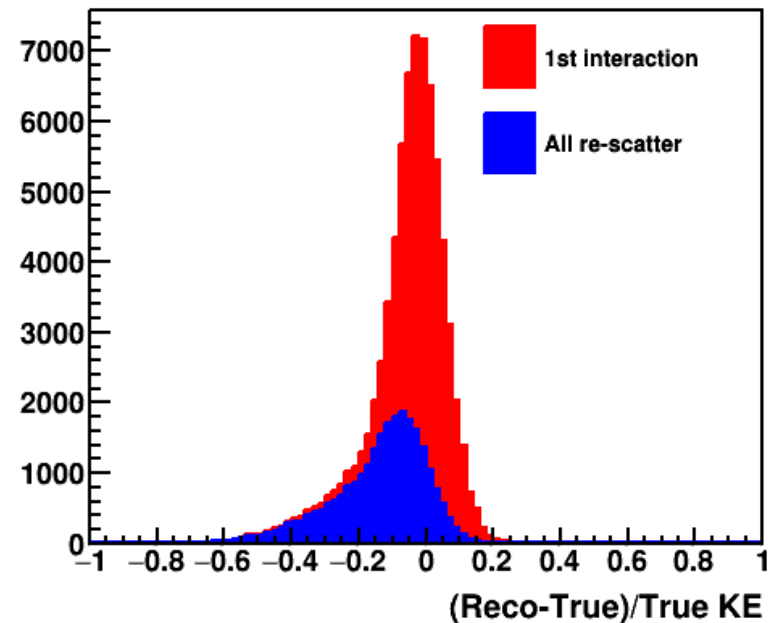

- Obviously, efficiency gets higher for thicker ECAL
- Around ~20 modules = ~44 cm thick, returns start diminishing
- Increase in efficiency is predominantly re-scatters, especially for higher energy neutrons

# Energy residual 50 MeV neutron

KE = 50 MeV, 20 modules, 100cm lever arm

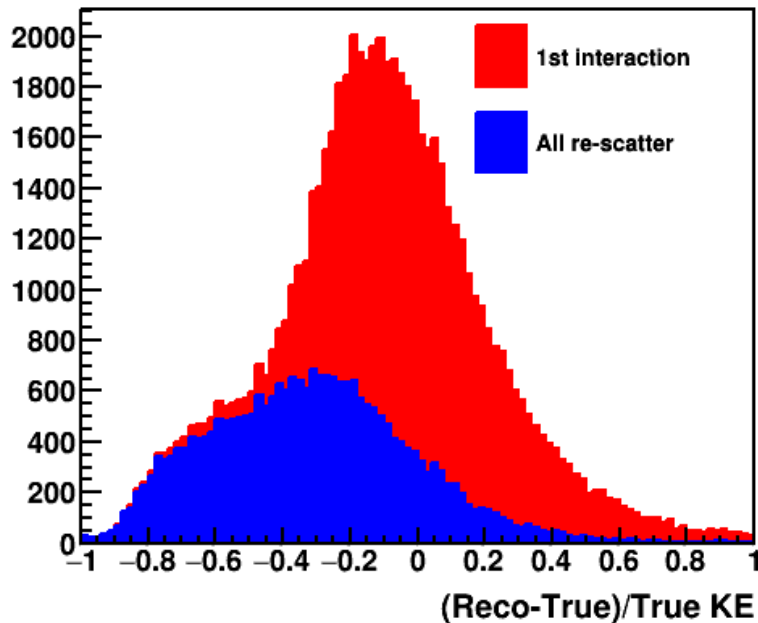

KE = 50 MeV, 20 modules, 300cm lever arm

- 100cm lever arm (left) is about the shortest F.V. distance you would get for gas TPC, 300cm (right) is closer to the middle of the TPC

# Energy residual 100 MeV neutron

KE = 100 MeV, 20 modules, 100cm lever arm

KE = 100 MeV, 20 modules, 300cm lever arm

- Energy resolution gets worse at higher energy due to reduced time of flight
- Re-scattering becomes more pronounced

# Energy residual 200 MeV neutron

KE = 200 MeV, 20 modules, 100cm lever arm

KE = 200 MeV, 20 modules, 300cm lever arm

- Energy resolution gets worse at higher energy due to reduced time of flight
- Re-scattering becomes more pronounced

# Energy residual 500 MeV neutron

KE = 500 MeV, 20 modules, 100cm lever arm

KE = 500 MeV, 20 modules, 300cm lever arm

- Bin at -1 is neutrons that reconstruct super-luminal, which is often at 100cm but non-existent at 300cm
- Resolution is still  $\sim 30\%$  for long lever arm even at 500 MeV, but with shelf due to missing first interaction

# Full spill simulation

# Analysis strategy

- “Neutron candidate” =  $>5$  MeV knock-out proton (or deuteron) in CH of ECAL
- For each gas TPC vertex, determine distance to inner-most neutron candidate
  - Draw  $30^\circ$  cone, with axis along straight line from vertex to knock-out proton
  - Collect any other in-time neutron candidates inside cone, and remove them (almost always due to re-scatters)
  - Repeat
- For each neutron candidate, determine distance to vertex
- Determine “search window”, starting with time at speed of light and ending with TOF for 50 MeV neutron
- Accept neutron candidate if it's in the time window

# Pile-up

- DUNE beam generates 1 neutrino interaction per spill per  $\sim 10$  tons
- Long lever arm  $\rightarrow$  long “search window”  $\rightarrow$  increased pile-up from neutrons produced outside gas TPC
- 3DST analysis has shown that pile-up is small for short lever arm, i.e. few ns search window, but for gas TPC search window is often few 10s of ns
- Following plots assume no rejection, which is conservative
  - Could veto on other activity in ECAL and reject background

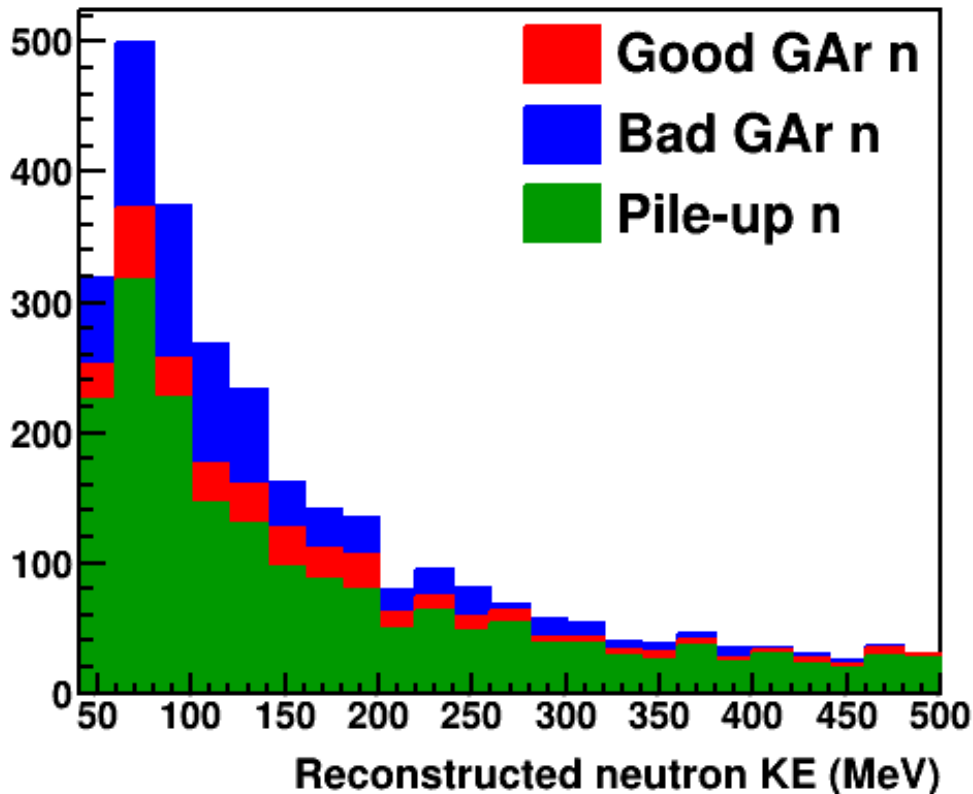

# Neutron energy distribution Inner ECal 20 modules

- This is 20 modules, so efficiency  $\sim 35\%$  for signal neutrons
- Purity is  $\sim 70\%$  at 50-100 MeV
- Low purity at high reconstructed energy because pile-up is flat in  $\Delta t$ , and there are few signal events at very high energies

# Neutron energy distribution

## Side outer ECal

- Outer side ECal contains almost no signal
- The little signal that does make it out there is poorly reconstructed
- So we definitely don't want to analyze these events

# Conclusions

- Neutron energy resolution from gas TPC + ECAL is excellent when first interaction can be identified, but ~30% of sample will be misreconstructed due to first interaction in passive absorber
- Efficiency is ~40% for 40cm of CH
- Pile-up is important – need to repeat study with detailed design including superconducting magnet
- Demonstrating ability to veto background is crucial

# Backup

# Why does it cut off at 50 MeV

- For 3m lever arm, high-energy neutron TOF is 10 ns
  - 50 MeV neutron is 31ns
  - 25 MeV neutron is 44ns
  - 10 MeV neutron is 69ns
- Arbitrarily choose 50 MeV as the cut-off velocity
- To go down to 25 MeV, window goes from 21ns to 34ns, and pile-up increases by 65%

# ECAL neutrons from rock neutrinos

Side rock

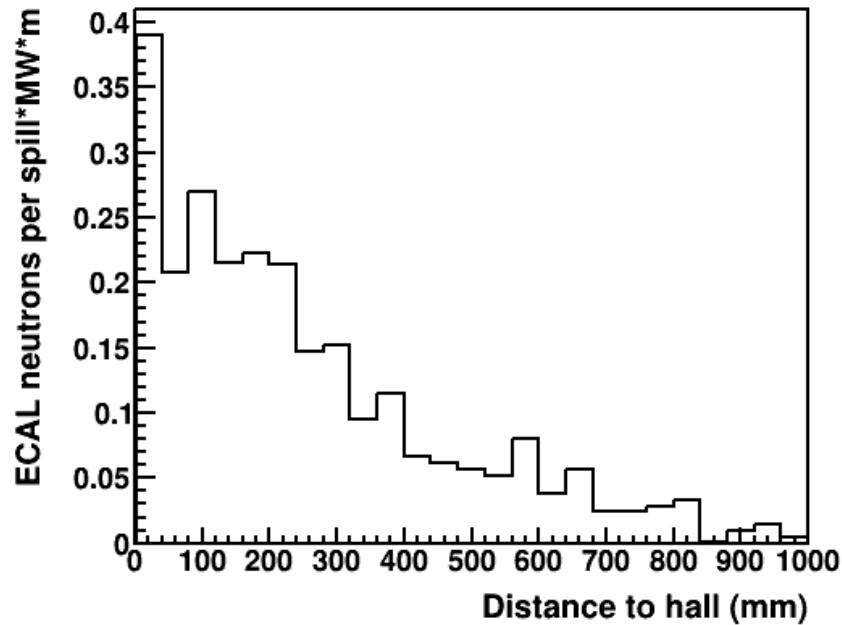

Upstream rock

- Look for  $>5$  MeV knock-out protons in ECal CH
- Plot distance from neutrino interaction to hall-rock boundary  
→ probability for a neutrino interaction to produce a neutron that is then reconstructed in the ECal

# ECAL neutrons from rock neutrinos

Side rock

Upstream rock

- Normalize to neutrons per spill\*MW per linear meter of rock
- Total  $\sim 1$  rock neutron per spill
- Many neutrons come into the hall, but few make it through the magnet
- Most of the rock  $\rightarrow$  ECal neutrons are actually charged particles interacting in the magnet and producing neutrons

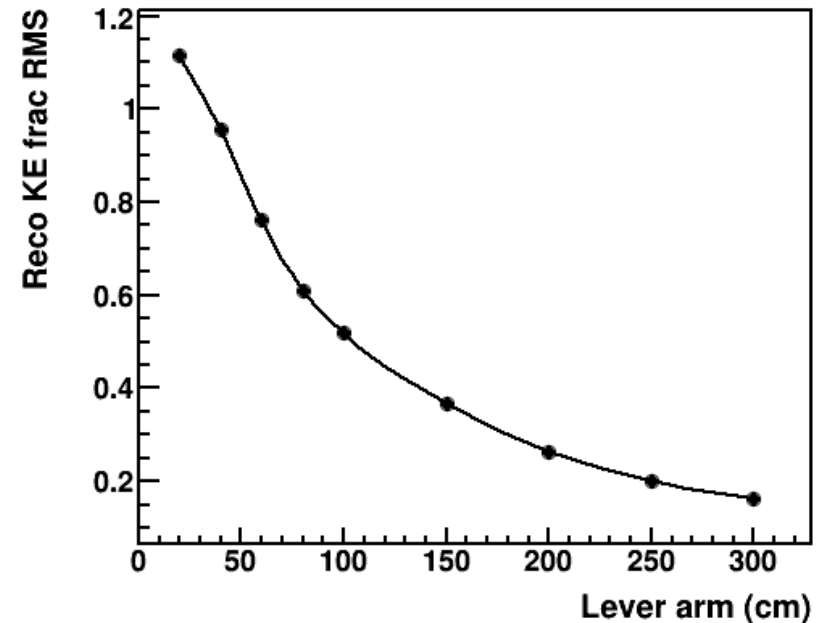

# Energy resolution vs lever arm

True KE 60 MeV

True KE 200 MeV

- For 60 MeV (left) and 200 MeV (right) neutrons
- Becomes very good for lever arm  $> 1\text{m}$
