

A Staged Muon-Based Neutrino and Collider Physics Program

The Muon Accelerator Program
(MAP) Collaboration

July 31, 2012

We sketch a staged plan for a series of muon-based facilities that can do compelling physics at each stage. Such a plan is unique in its ability to span both the Intensity and Energy Frontiers as defined by the P5 sub-panel of the US High Energy Physics Advisory Committee [1]. This unique physics reach places a muon-based facility in an unequaled position to address critical questions about the nature of the Universe. An R&D program in support of the plan is in progress under the auspices of the US Muon Accelerator Program [2]. The plan is conceived in four stages, whose exact order remains to be worked out:

- The “entry point” for the plan is the ν STORM facility proposed at Fermilab, which can advance short-baseline physics by making definitive observations or exclusions of sterile neutrinos. Secondly, it can make key measurements to reduce systematic uncertainties in long-baseline neutrino experiments. Finally, it can serve as an R&D platform for demonstration of accelerator capabilities pre-requisite to the later stages.
- A stored-muon-beam Neutrino Factory can take advantage of the large value of θ_{13} recently measured in reactor-antineutrino experiments to make definitive measurements of neutrino oscillations and their possible violation of CP symmetry.
- Thanks to suppression of radiative effects by the muon mass and the m_{lepton}^2 proportionality of the s -channel Higgs coupling, a “Higgs Factory” Muon Collider can make uniquely precise measurements of the 126 GeV boson recently discovered at the LHC.
- An energy-frontier Muon Collider can perform unique measurements of Terascale physics, offering both precision and discovery reach.

Stored-muon-beam facilities have been shown to be feasible in a number of studies. They exploit the relatively long muon lifetime of $2.2 \mu\text{s}$ together with relativistic time dilation and rapid acceleration technologies. These advantages make muons the “lepton of choice” for a variety of physics goals. The plan thus has the right “footprint” to be the next major arena for High Energy Physics, complementing the LHC, over the next two decades.

In the following we first summarize the physics landscape to which muon facilities can contribute. We then briefly describe the main features of stored-muon-beam facilities. They present unparalleled near- and far-term opportunities that ideally will be exploited through cooperation among the regions of the High Energy Physics world.

1 Short-Baseline Neutrino Physics

In the present context, short-baseline physics refers to those neutrino flavor conversion/disappearance phenomena which take place at L/E values considerably smaller than those

typically associated with the mass-squared splittings of atmospheric and solar neutrino oscillations. In the last 18 months, this area has seen a greatly increased scientific interest, resulting in a number of workshops and documents, notably the sterile neutrino white paper [3] and the report of the short-baseline focus group at Fermilab [4]. Therefore, it is sufficient to summarize here the hints for oscillations at $L/E \sim 1 \text{ m/MeV}$ and refer the reader to the aforementioned reports for more details.

There are the LSND [5] and now MiniBooNE [6] results which indicate a flavor conversion of $\bar{\nu}_\mu$ to $\bar{\nu}_e$ at the level of about 0.003. At the same time MiniBooNE has seen a low-energy excess of events which may or may not be related to their and LSND's primary signal.

The results from calibrations of low-energy radiochemical solar-neutrino experiments using the reaction $\nu_e + \text{Ga} \rightarrow \text{Ge} + e^-$ based on artificial, monoenergetic neutrino sources (^{51}Cr and ^{37}Ar) show a deficit in count rate of about 25% with an uncertainty of about 10% [7, 8].

The so-called reactor anomaly [8] indicates a 6% deficit of $\bar{\nu}_e$ emitted from nuclear reactors at baselines less than 100 m. Interestingly, this is entirely based on the re-analysis of existing data; the deficit is caused by three independent effects which all tend to increase the expected neutrino event rate. There have been two re-evaluations of reactor antineutrino fluxes [9]; both see an increase of flux by about 3%. The neutron lifetime decreased from 887–899 s to 885.7 s [10] and thus the inverse β -decay cross section increased by a corresponding amount. The contribution from long-lived isotopes to the neutrino spectrum was previously neglected and enhances the neutrino flux at low energies.

All these hints together have a statistical significance exceeding 3σ and may be caused by one or more sterile neutrinos with a mass of roughly 1 eV.

There is also a somewhat ambiguous indication from cosmology of more relativistic degrees of freedom in the early Universe than the Standard Model allows, while large-scale-structure data disfavor the existence of a fourth neutrino with a mass in the eV range.

To resolve these anomalies a new series of experiments is necessary and warranted. Several proposals exist, at both Fermilab and CERN, to use pion decay-in-flight beams, as MiniBooNE did; crucial differences from MiniBooNE would be use of a near detector and, potentially, of LAr TPCs instead of scintillator detectors. While these new proposals would constitute a significant step beyond what MiniBooNE has done, especially in terms of systematics control, it remains to be proven that a beam with a 1%-level contamination of ν_e can be used to perform a high-precision study of a sub-percent ν_e appearance effect. In particular, many of these proposals involve near and far detectors of very different sizes and/or geometrical acceptance, and thus cancellations of systematics will be far from perfect.

The other proposed technology is a stored muon beam (“ ν STORM”) [11]. Here, the neutrinos are produced by the purely leptonic, and therefore well understood, decay of muons, thus the neutrino flux can be known with very high, sub-percent, precision. The signals are wrong-sign muons which can be identified quite easily in a magnetized-iron detector. The precise knowledge of neutrino flux and expected very low backgrounds for the wrong-sign muon search allow reduction of systematics to a negligible level, hence permitting precise measurements of the new physics that may be behind the short-baseline anomalies.

2 Long-Baseline Neutrino Physics

With the discovery of a large value for θ_{13} , the physics case for the next generation of long-baseline neutrino-oscillation experiments has grown considerably stronger and one of the major uncertainties on their expected performance has been removed. The remaining questions are: the value of the leptonic CP phase and the quest for CP violation; the mass hierarchy; whether θ_{23} is maximal and, if not, whether it is larger or smaller than $\pi/4$; and of course, the search for new physics beyond the three-active-neutrinos paradigm. Based on our current, incomplete understanding of the origin of neutrino mass and the observed flavor structure in general, it is very hard to rank these questions in relative importance, but with the large value of θ_{13} it is feasible to design and build a long-baseline facility which can address all three questions with high precision and significance.

The error on θ_{13} will keep decreasing as the reactor measurements are refined, and Daya Bay is expected to yield a precision which would be surpassed only by a neutrino factory. It is an important test of the three-flavor oscillation model to see whether the value extracted from disappearance at reactors matches that from appearance in beams.

A combination of the existing experiments with future T2K, NO ν A, and reactor data will allow a first glimpse of the mass hierarchy, and, for favorable CP phases, and with extended running, a 5σ determination may be possible. Also, new atmospheric neutrino experiments such as PINGU, ICAL at INO, and Hyper-K have, in principle, some sensitivity to the mass hierarchy, although the actual level of significance will depend strongly on the achievable angular and energy resolution for the incoming neutrino. There are also plans for a dedicated experiment, Daya Bay 2, which would rely not on matter effects but on measuring the interference of the two mass-squared differences at a distance of about 60 km from a nuclear reactor. It thus seems likely that global fits will provide a $3\text{--}5\sigma$ determination of the mass hierarchy by about 2020. Nonetheless, a direct and precise test of matter effects and determination of the mass hierarchy from a single measurement would be valuable.

A commonly used paradigm for neutrino physics beyond oscillations is so-called non-standard interactions (NSI). These can arise in many different models and their phenomenology is easy to capture in a model-independent way. Large θ_{13} means that interference of oscillation amplitudes proportional to $\sin 2\theta_{13}$ with NSI effects can enhance NSI sensitivity substantially. If NSI are present, the extraction of the mass hierarchy from global fits is unlikely to yield the correct result. Also, NSI are a straightforward mechanism to induce a difference between reactor and beam measurements of θ_{13} . Longer baselines generally have more sensitivity to NSI and also allow a better separation of oscillation from NSI.

The central physics goal of future long-baseline experiments is the measurement of the leptonic CP phase and, potentially, the discovery of leptonic CP violation. It is important to distinguish these two goals: with large θ_{13} a measurement of the CP phase to a given precision can be virtually guaranteed; however, CP violation may or may not be present in the lepton sector. We thus focus on the measurement of the CP phase since the discovery reach for CP violation directly derives from it. A determination of the CP phase requires measurement of any two of the following four transitions: $\nu_e \rightarrow \nu_\mu$, $\bar{\nu}_e \rightarrow \bar{\nu}_\mu$, $\nu_\mu \rightarrow \nu_e$, $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$. However, with long baselines, there will always be matter effects, which also contribute CP asymmetries; it is thus necessary to separate this contribution from CP violation in the mixing matrix. This separation is greatly facilitated by exploiting L/E information,

ideally spanning a wide enough interval that more than one node of the oscillation can be resolved. This requirement, in combination with limitations of neutrino sources and detectors, implies that baselines longer than 1,000 km are needed [12]. This is borne out in the LBNE reconfiguration discussion: shorter baselines, such as those of the existing NuMI beamline, require generally a larger exposure to reach the same CP sensitivity.

For “superbeam” experiments, systematic uncertainties will be a major issue, since neither detection cross sections nor beam fluxes are known to the required precision, and thus near detectors together with hadron-production data will play an important role. However, these alone will not provide percent-level systematics, since the beam at the near detector is composed mostly of ν_μ , precluding a measurement of the ν_e cross section, but in the far detector the signals are ν_e (see e.g. [13]). Unfortunately, there are no strong theory constraints on the ratio of muon- to electron-neutrino cross sections [14]. To provide an independent constraint on the electron (anti)neutrino cross section, a facility such as ν STORM is crucial.

Figure 1 compares CP precision for various facilities. The 10 GeV neutrino factory (labeled LENF) is the only facility approaching the CKM precision, and has the potential even to go beyond that. The “superbeams” LBNE, LBNO, and T2HK, and the “2020” global fit, span a very wide range of precision, demonstrating the crucial importance of achieving sufficient statistics. The number of events is determined by the product of beam power, detector mass and running time, each of which can easily vary by an order of magnitude. LBNO has recently submitted an expression of interest [15] to CERN outlining a much smaller detector and lower beam power, which would put its CP precision close to that of any of the reconfigured LBNE options.

The sensitivity of these results to assumptions about systematics is not shown in the figure, but important differences exist. For example, T2HK exhibits a very strong sensitivity to the assumed level of systematics [16] and thus is significantly more at risk of being systematics-limited. Due to their long baselines and resultant wide L/E coverage, both the LBNE Homestake option and LBNO are quite safe from systematics [16]. At the current stage all of these experiments must rely on assumptions about their systematics. In any comparison such as that of Fig. 1, the relative performance can vary greatly depending on these assumptions. In the end, *both* sufficient statistics and small systematics will be required in order to perform a precise measurement of the CP phase.

It is worth noting that a neutrino factory with only 1/40th of its design exposure has a physics performance similar to that of LBNE with 10 kt and 700 kW. This low-luminosity neutrino factory could naturally evolve from ν STORM and a detector located between 1,300 and 2,300 km from the accelerator. For this exposure, no muon cooling is needed, and a proton beam of 700 kW at 60–120 GeV with a 10–15 kt detector running for 2×10^8 s would suffice. Increased beam power and the addition of muon cooling would allow eventually reaching the full neutrino factory exposure. A lower-energy option with ≈ 5 GeV stored-muon energy is also feasible and provides comparable physics sensitivities. In this case, to match the lower energy, the baseline should not exceed 1,500 km.

3 Neutrino Physics Summary

A staged muon-based program starting with ν STORM, which can evolve in various, adjustable steps to a full Neutrino Factory and pave the way towards a Muon Collider, seems

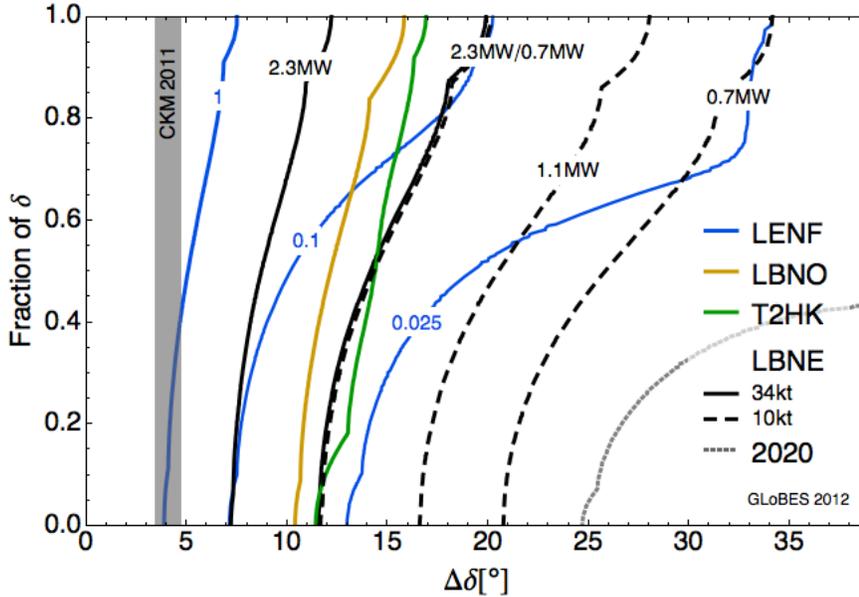

Figure 1: Fraction of values of the CP phase, δ , for which a given 1σ precision $\Delta\delta$ can be achieved, for facilities indicated in the legend: LBNF, a 10 GeV neutrino factory with 1.4×10^{22} useful muon decays, using 4 MW proton-beam power for 10^8 s, 2,000 km baseline and a 100 kt magnetized iron detector; LBNO, a 100 kt LAr detector at a baseline of 2,300 km and 10^{22} pot at 50 GeV (about 800 kW of beam power for 10^8 s); T2HK, a 560 kt water-Cherenkov detector at 295 km using a 1.66 MW beam for 5×10^7 s (equivalent to 1.2×10^8 s at 700 kW); LBNE, using LAr detectors of either 10 kt or 34 kt at a distance of 1,300 km for 2×10^8 s with beam powers as indicated in the legend; “2020,” results from a combined fit to nominal runs of T2K, NO ν A and Daya Bay. All detector masses are fiducial. The vertical gray shaded area, labeled “CKM 2011”, indicates the current uncertainty on the CP phase in the CKM matrix. Calculations include near detectors and assume consistent flux and cross-section uncertainties. (Plot courtesy P. Coloma [16].)

a very attractive option. It will produce outstanding physics at each stage.

4 Collider Physics Landscape

The Standard Model (SM) has been a spectacular success. For more than thirty years, all new observations except for neutrino mass have fit naturally into this framework. But basic questions remain: (1) Is the Higgs mechanism the correct mechanism of electroweak symmetry breaking? (2) How do the fermion masses and flavor mixings arise? Furthermore, the Standard Model is incomplete. It does not explain dark matter; neutrino masses and mixings require new particles or interactions; and the observed baryon asymmetry in the universe requires additional sources of CP violation. From a theoretical viewpoint there are also problems with the SM. It has been argued by G. 't Hooft that the SM is not natural at any energy scale μ much above the Terascale (~ 1 TeV) because the small dimensionless parameter $\epsilon(\mu) = (m_H/\mu)$ is not associated with any symmetry as $\epsilon \rightarrow 0$ [17]. This is the naturalness problem of the SM. If the SM is valid all the way up to the Planck scale ($\Lambda_{Pl} \sim$

10^{19} GeV), then the SM has to be fine-tuned to a precision of one part in $(m_H/\Lambda_{PL})^{-2}$! In this decade, the physics of the Terascale will be explored at the LHC. Planned experiments studying neutrino oscillations, quark/lepton flavor physics, and rare processes may also provide insight into new physics at the Terascale and beyond.

Discoveries made at the LHC will elucidate the origin of electroweak symmetry breaking. Is that mechanism just the SM Higgs scalars or does it involve new physics? New physics might be new gauge bosons, additional fermion generations or fundamental scalars. It might be SUSY or new dynamics or even extra dimensions. Significant theoretical questions will likely remain even after the full exploitation of the LHC—most notably, the origin of fermion (quark and lepton) masses, mixings and CP violation; the character of dark matter; and detailed questions about spectrum, dynamics, and symmetries of any observed new physics. Thus, it is hard to imagine a scenario in which a multi-TeV lepton collider would not be required to fully explore the new physics.

To prepare for the energy frontier in the post-LHC era, research and development is being pursued on a variety of lepton colliders: a low-energy ($E_{cm} < 1$ TeV) linear electron-positron collider (ILC), a second design (CLIC) capable of higher energies ($E_{cm} = 3$ TeV), and a multi-TeV Muon Collider.

A multi-TeV Muon Collider provides a very attractive possibility for studying the details of Terascale physics after the LHC. Physics and detector studies are under way to understand the required collider parameters (in particular luminosity and energy) and map out, as a function of these parameters, the associated physics potential. The physics studies will set benchmarks for various new-physics scenarios (e.g., SUSY, Extra Dimensions, New Strong Dynamics) as well as Standard Model processes.

Furthermore, the Muon Collider lends itself to a staged program with physics at each stage of producing and cooling the muons. Important physics opportunities include the possibility of a Higgs Factory and/or a Neutrino Factory as steps to a Muon Collider.

5 Muon Collider Physics

The Muon Collider is an energy-frontier machine. It offers both discovery as well as precision measurement capabilities. The physics goals of a Muon Collider (MC) are for the most part the same as those of a linear electron-positron collider at the same energy (CLIC) [18, 19]. The main advantages of a MC are the ability to study the direct (s -channel) production of scalar resonances, a much better energy resolution (because of the lack of significant beamstrahlung), and the possibility of extending operations to very high energies. (Ideas for $E_{cm} \geq 6$ TeV are being entertained.) At CLIC, however, significantly greater polarization of the initial beams is possible [19]. Furthermore, CLIC is free of the significant detector backgrounds found in a MC due to muon decays upstream of the interaction point.

There are basically three kinds of channels of interest for a lepton collider: (1) open pair production, (2) s -channel resonance production, and (3) fusion processes.

5.1 Pair Production

The kinematic thresholds for pair production of standard model particles ($X + \bar{X}'$) are well below $E_{cm} = 500$ GeV. For standard model particles at $E_{cm} > 1$ TeV the typical

open-channel pair-production process is well above its kinematic threshold and R (the cross section normalized to that for annihilation into electron-positron pairs) becomes nearly flat.

For the MC a forward/backward angular cut (e.g., 10°) is imposed on the outgoing pair. Closer to the beam direction, a shielding wedge is needed to suppress detector backgrounds arising from the effects of muon decay in the beams.

For a process whose rate is one unit of R , an integrated luminosity of 100 fb^{-1} at $E_{cm} = 3 \text{ TeV}$ yields 1000 events. For example, the rate of top-quark pair production at 3 TeV is only 1.86 units of R . This clearly demonstrates the need for high luminosity in a multi-TeV lepton collider.

5.2 Resonances

Many models beyond the SM predict resonances that may be produced directly in the s channel at a Muon Collider. Here, the narrow beam energy spread of a Muon Collider, $\delta E/E \sim \text{few} \times 10^{-5}$, could be an important advantage. The cross section for the production of an s -channel resonance, X , with spin J , mass M and width Γ is given by

$$\sigma(\mu^+\mu^- \rightarrow X) = \frac{\pi}{4k^2}(2J+1)\frac{\gamma^2}{(E-m)^2 + \Gamma^2/4}B_{\mu^+\mu^-}B_{\text{visible}}, \quad (1)$$

where k is the momentum of the incoming muon and E the total energy of the initial system (E_{cm}). $B_{\mu^+\mu^-}\Gamma$ is the partial width of $X \rightarrow \mu^+\mu^-$ and B_{visible} is the visible decay width of X . At the peak of the resonance with negligible beam energy spread, we have

$$R_{\text{peak}} = 3(2J+1)\frac{B_{\mu^+\mu^-}B_{\text{visible}}}{\alpha_{\text{EM}}^2}. \quad (2)$$

5.2.1 Z'

For a sequential standard model Z' gauge boson, the value of R_{peak} is strikingly large, typically $\sim 10^4$. The luminosity, L , for $1.5 < M(Z') < 5.0 \text{ TeV}$ required to produce 1000 events on the Z' peak is only $0.5\text{--}5.0 \times 10^{30} \text{ cm}^{-2} \text{ s}^{-1}$. Hence, a comprehensive first-order study of the properties of a narrow resonance, such as a Z' , in the few-TeV mass range can be carried out with a low-luminosity, $L \sim 10^{30} \text{ cm}^{-2} \text{ s}^{-1}$, Muon Collider.

5.2.2 Extra Dimensions

Theories with extra dimensions that have a radius of curvature close to the Terascale have been postulated. Here one expects an excitation spectrum, arising from excited modes in the extra dimension, for the graviton and any other SM particles whose interactions occur in the bulk. In the Randall-Sundrum warped extra dimensions models [20], the graviton spectrum contains additional resonances (KK-modes) that can be probed by a Muon Collider.

From the perspective of energy frontier colliders, however, only the physics at the first (perhaps second) Kaluza-Klein (KK) mode will be relevant. All kinematically allowed KK-mode resonances are accessible to a multi-TeV Muon Collider. These include the Z' and γ' of the electroweak sector. The precise measurement of the Z' and γ' mass scales will determine the various electroweak symmetry-breaking structures, and how these states couple to different fermion generations will determine bulk fermion localization.

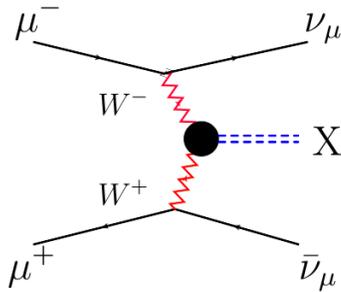

Figure 2: Typical fusion process.

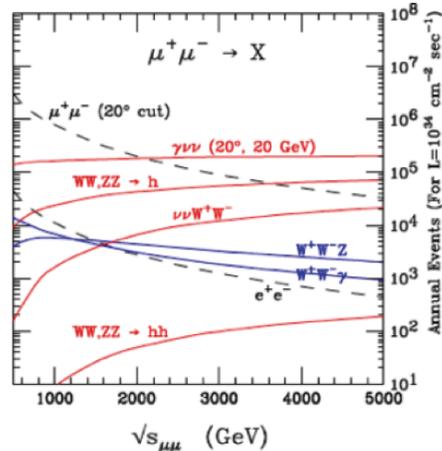

Figure 3: Various fusion cross sections versus \sqrt{s} at lepton colliders.

5.3 Fusion Processes

A typical fusion process is shown in Fig. 2. For $E_{cm} \gg M_X$ the cross section is typically large and grows logarithmically with $s = E_{cm}^2$; while the usual pair-production processes are constant in R and thus dropping like $1/s$. Thus, for asymptotically high energies, fusion processes dominate. For lepton colliders, the crossover occurs in the few-TeV region in standard model processes, as shown in Fig. 3. A variety of processes are shown including WW and ZZ inclusive production. The large rates for WW , WZ , and ZZ fusion processes imply that the multi-TeV Muon Collider is also effectively an electroweak-boson collider.

Physics studies of fusion processes such as $\mu^+\mu^- \rightarrow Z^*Z^*\mu^+\mu^- \rightarrow X\mu^+\mu^-$ benefit greatly by tagging of the outgoing μ^\pm and hence will be sensitive to the required $\approx 10^\circ$ angular cut.

6 Standard Model Higgs Boson

Both the ATLAS [21] and CMS [22] experiments at the LHC have observed a new boson with a mass about 126 GeV. Further data will be required to establish the spin ($J = 0$ or 2), parity, and determine whether the branching ratios to various final states are consistent with the Standard Model Higgs boson. But whatever the results, it is clear that more precise studies of this new boson will be an important target of future lepton colliders. A Muon Collider Higgs Factory has the unique ability to allow the direct measurement of the width of the Higgs-like boson.

Studies of the feasibility of direct production of the SM Higgs boson were carried out over a decade ago [23] for a low-energy, high-luminosity MC. It was found that very precise control of the beam energy and energy spread are required. The discovery of a new Higgs-like boson at the LHC has renewed interest in a Muon Collider Higgs Factory [24].

Higgs bosons can be studied in a number of other ways at a multi-TeV Muon Collider:

1. Associated production: $\mu^+\mu^- \rightarrow Z^* \rightarrow Z^0 + h^0$ has $R \sim 0.12$. We can measure the b -quark Higgs-Yukawa coupling and look for invisible decay modes of the Higgs boson.

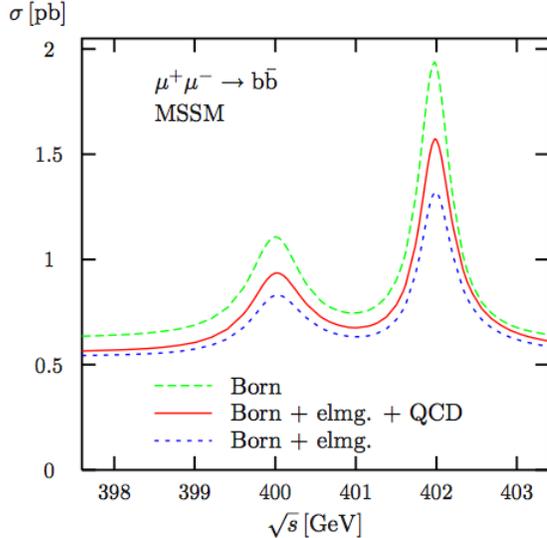

Figure 4: MSSM cross section $\mu^+\mu^- \rightarrow b\bar{b}$ near the H^0 and A resonances (with $M_A = 400$ GeV and $\tan\beta = 5$). SM radiative corrections to the lowest-order processes have been included. (From [26].)

2. Higgsstrahlung: $\mu^+\mu^- \rightarrow t\bar{t} + h^0$ has $R \sim 0.01$ (so such a study requires $\sim 5 \text{ ab}^{-1}$). This could provide a direct measurement of the top quark Higgs-Yukawa coupling.
3. W^*W^* fusion into $\bar{\mu}_\mu\nu_\mu + h^0$ has $R \sim 1.1 \ln s$ (for $m_h = 120$ GeV). It allows the study of Higgs self-coupling and certain rare decay modes.

7 Extended Higgs Sector

In the two-Higgs doublet scenario there are five scalars: two charged scalars H^\pm , two neutral CP-even scalars h, H^0 , and a neutral CP-odd scalar A . Two Higgs doublets occur naturally in supersymmetric models [25]. For the constrained MSSM model (cMSSM), as the mass of the A is increased, the h becomes closer to the SM Higgs couplings and the other four Higgs become nearly degenerate in mass. This makes resolving the two neutral-CP states difficult without the good energy resolution of a Muon Collider, as shown in Fig. 4.

8 Supersymmetry

Supersymmetry (SUSY) provides a solution to the naturalness problem of the SM. It is a symmetry that connects scalars with fermions, ordinary particles with superpartners: a symmetry that is missing in the SM.

The simplest SUSY model is the constrained MSSM, with only five parameters determining the masses of all the superpartners. cMSSM scenarios are now highly constrained by the direct observation of a new Higgs-like boson at a mass of 126 GeV [27]. Powerful constraints on cMSSM are also provided by the electroweak precision measurements and the lack of any indications of SUSY from flavor physics so far [?].

Arbey *et al.* [27] found that cMSSM models with minimal anomaly- or gauge-mediated supersymmetry breaking are now disfavored as these models predict a too light Higgs particle. The gravity-mediated constrained MSSM would still be viable, provided the scalar top quarks are heavy and their trilinear coupling large. Significant areas of the parameter space of models with heavy supersymmetric particles, such as split or high-scale supersymmetry, could also be excluded as, in turn, they generally predict a too heavy Higgs particle [27].

To date, no evidence for SUSY particles has been found at the LHC. In particular, ATLAS [29] and CMS [30] have produced strong direct bounds on the masses of squarks and gluinos below 1 TeV.

All this, taken together, makes it almost certain that direct coverage of the remaining MSSM parameter space requires a multi-TeV-scale lepton collider such as CLIC or a Muon Collider.

9 New Strong Dynamics

Strong dynamical models of electroweak symmetry breaking have no elementary scalars and thus avoid the naturalness problem of the SM. Chiral symmetry breaking (à la QCD) in the technicolor sector produces technipions that give the proper masses to the W and Z bosons. For details and a discussion of various new strong dynamics models see the review of Hill and Simmons [31].

The minimal Technicolor model contains an isospin triplet techni-rho (ρ_T) and singlet techni-omega (ω_T) vector mesons, which can be produced in the s channel in lepton colliders. In addition, it contains a techni-eta' (η'_T) which would be produced in association with Z bosons in analogy to the Higgs boson.

In less minimal schemes, there are residual techni-pions, π_T^\pm and π_T^0 , that can be produced in lepton colliders. The techni-rho is typically broad if the two-techni-pion channel is open but, as in QCD, the techni-omega is nearly degenerate and narrow. In low-scale Technicolor models, some techni-rho (ρ_T) can be light (~ 250 GeV) as well as nearly degenerate in mass with a techni-omega, and these can be studied in great detail at a Muon Collider with the appropriate energy [31]. For techni-rho and techni-omega masses in the TeV range, a CLIC study has been done to determine its resolving power. The results for a Muon Collider are essentially the same as the CLIC curve before inclusion of beamstrahlung and ISR effects. For this physics, the Muon Collider has a distinct advantage over CLIC. The comparison is shown in Fig. 5.

There are other approaches to new strong dynamics: Topcolor, TC2, composite and Little Higgs models [31]. All of these would provide a rich spectrum of states that can be observed at a multi-TeV Muon Collider.

10 Contact Interactions

New physics can enter through contact interactions, which are higher-dimension operators in the effective Lagrangian, as

$$\mathcal{L} = \frac{g^2 \bar{\psi} \Gamma \psi \bar{\psi} \Gamma \psi}{\Lambda^2}. \quad (3)$$

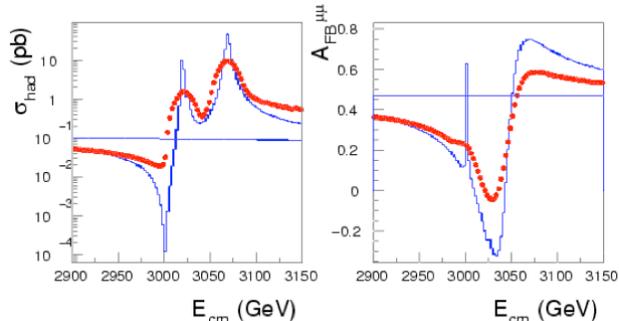

Figure 5: D-BESS model at CLIC [32, 33]. CLIC energy resolution limits ability to disentangle nearby states expected in models with new strong dynamics.

The MC is sensitive to $\Lambda \sim 200$ TeV, roughly equivalent to CLIC. Preliminary studies suggest that the forward-angle cut is not an issue here [34]. If polarization is not available at a MC, it may be at a disadvantage compared with CLIC in the ability to disentangle the chiral structures of the new operators (see Fig. 6).

11 Muon Collider Physics Summary

A multi-TeV Muon Collider is required for the full coverage of Terascale physics. The physics potential for a Muon Collider at ~ 3 TeV and integrated luminosity of 1 ab^{-1} is outstanding. Particularly strong cases can be made if the new physics is SUSY or new strong dynamics. Furthermore, a staged muon collider can provide a Neutrino Factory to fully disentangle neutrino physics. If a narrow s -channel resonance state exists in the multi-TeV region, the physics program at a Muon Collider could begin with less than $10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ luminosity.

The observation of a new state at 126 GeV by both ATLAS and CMS revitalizes consideration of a Higgs factory as part of a staged multi-TeV muon collider. This is particularly attractive if there is an enlarged scalar sector (e.g., THDM, SUSY). Many details will remain to be understood even after the LHC.

Detailed studies of the physics case for a multi-TeV muon collider are just beginning. The goals of such studies are to: (1) identify benchmark physics processes; (2) study the physics dependence on beam parameters; (3) estimate detector backgrounds; and (4) compare the physics potential of a Muon Collider with those of the ILC, CLIC and upgrades to the LHC.

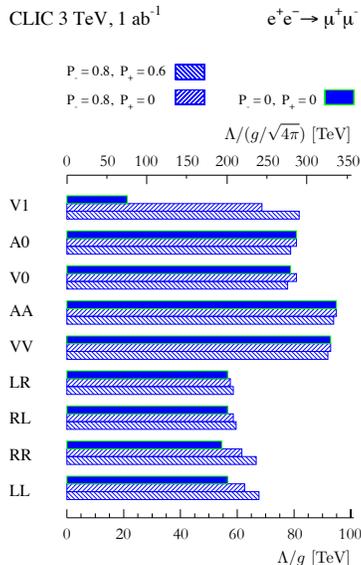

Figure 6: Reach of a lepton collider for contact terms with various chiral structure. The role of polarization is indicated. (From [19].)

12 A Staged Muon Accelerator Program

To elaborate on points already mentioned, advantages of muon over electron colliders are:

1. Synchrotron radiation, proportional to E^4/m^4 , is strongly suppressed for muons, allowing circular machines much smaller than an e^+e^- collider of comparable energy.
2. Each muon bunch thus collides repeatedly, allowing larger emittances and fewer leptons for a given luminosity. The number of collisions per machine cycle is limited by the muon lifetime to ≈ 150 times the average bending field (typically 7 T), corresponding to ~ 1000 turns, and thus this number of bunch crossings in each detector. In contrast, in an electron-positron linear collider the beams interact only once.
3. In a circular collider ring, there can be more than one detector (two in our design), which effectively doubles the luminosity.
4. Radiation during bunch crossings (beamstrahlung) is also proportional to E^4/m^4 , giving a much smaller energy spread at a Muon Collider than at an e^+e^- collider.
5. s -channel Higgs production is enhanced by the factor $(m_\mu/m_e)^2 \approx 40,000$, making exploitation of such production practicable, whereas with electrons it is not.

Muon accelerators require technologies already in use, or that are straightforward extensions of the current state of the art: linacs and recirculating linear accelerators (RLAs) are already fast enough for muon acceleration. The focus of muon-acceleration R&D is thus cost reduction, which can be achieved by means of newly developed fixed-field alternating gradient accelerators (FFAGs) and very-rapid-cycling synchrotrons.

Achieving the μm -scale beam emittances desired for high luminosity is more challenging, but feasible via ionization cooling [35]. In this, the muons are alternately passed through energy-absorbing media and reaccelerated by means of RF cavities, while being strongly focused by superconducting solenoids in order to overcome the heating effects of multiple Coulomb scattering. The evolution with path-length s of the normalized transverse emittance ϵ_n of muons of energy E_μ , mass m_μ , and speed β traversing a material medium is given by [36]

$$\frac{d\epsilon_n}{ds} \approx -\frac{1}{\beta^2} \left\langle \frac{dE_\mu}{ds} \right\rangle \frac{\epsilon_n}{E_\mu} + \frac{1}{\beta^3} \frac{\beta_\perp (0.014 \text{ GeV})^2}{2E_\mu m_\mu X_0}, \quad (4)$$

where β_\perp is the lattice focal length and X_0 the radiation length of the medium. The large dE/ds ($4.0 \text{ MeV}/(\text{g}/\text{cm}^2)$) and long radiation length ($61.3 \text{ g}/\text{cm}^2$) of hydrogen make it, and such compounds as LiH, the media of choice, while solenoids with fields up to 30 T are in development. Together these allow transverse emittances down to $\sim 10 \mu\text{m}$ to be achieved—a reduction factor of 10^6 in six-dimensional emittance—enabling $\sim 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ luminosity. The MICE experiment [37] in progress at the UK's Rutherford Appleton Laboratory will demonstrate muon ionization cooling and, starting in 2013, provide measurements needed for detailed validation of the simulation codes used to design ionization cooling channels.

The remaining ingredients for colliders of such luminosity are multi-megawatt proton beams and targets; these have been developed for spallation neutron sources, and the MERIT experiment at CERN has established the feasibility of the configuration of choice

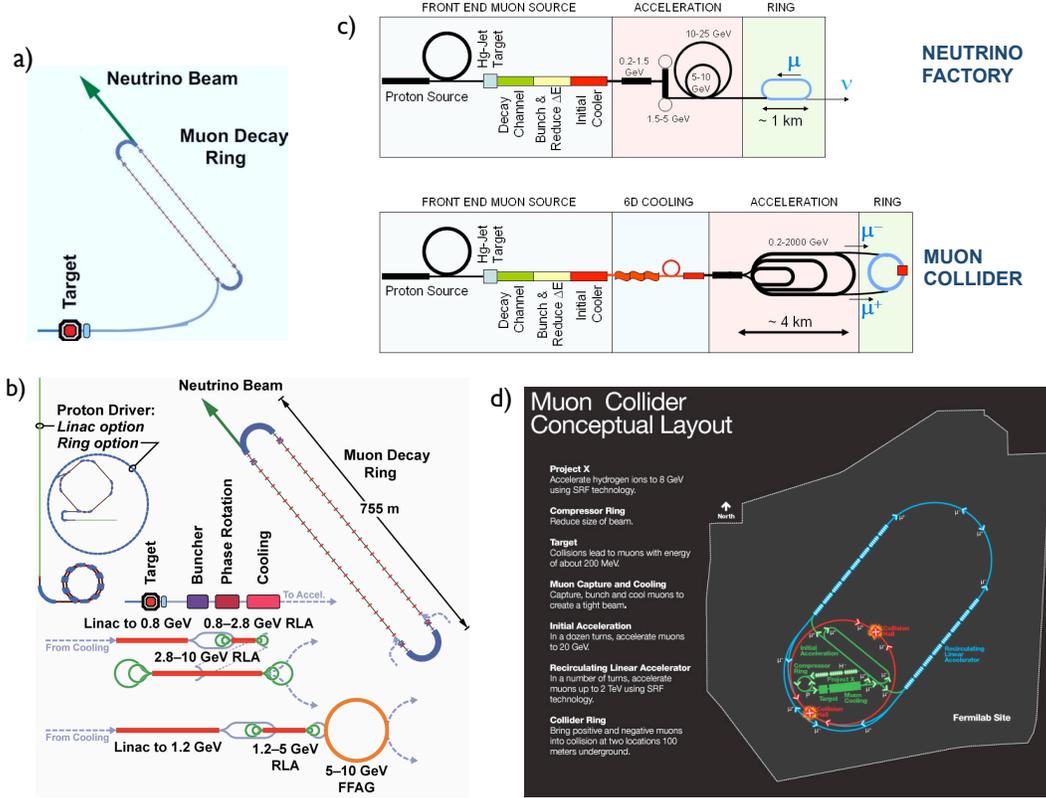

Figure 7: Ingredients for a possible muon-facility staging plan: a) ν STORM; b) IDS-NF Neutrino Factory; c) Muon Collider as Neutrino Factory upgrade; d) possible siting of multi-TeV Muon Collider at Fermilab.

for muon facilities: a free-flowing mercury jet in a high-field (≈ 15 T) hybrid copper-insert/superconducting-outsert pion-capture solenoid. The “Project X” accelerator proposed at Fermilab is suitable and can be upgraded to the beam power that will ultimately be needed.

The same technologies, albeit in less demanding incarnations, enable Neutrino Factories producing beams of $\sim 10^{21}$ electron and muon neutrinos per year aimed at remote detectors over $\sim 1,000$ km baselines. In particular, a factor ~ 10 in emittance reduction suffices for such a high-luminosity Neutrino Factory, and, as mentioned, an entry-level facility without cooling, to which cooling could be added as an upgrade, is already of considerable interest. Adding a true NF front-end to ν STORM could increase the flux a factor of 10–50, and the decay ring magnets could then be reused in a new tunnel oriented on a longer baseline.

The International Design Study for a Neutrino Factory (IDS-NF) is targeting a Reference Design Report on the 2013 timescale. In the US, the Muon Accelerator Program (MAP) is in progress with the goal of completing the R&D necessary to validate the Muon Collider concept on a 6-year timescale.

Ingredients for a possible staging sequence are illustrated in Fig. 7. Since the LHC boson discovery and measurement of θ_{13} are so recent, whether a Neutrino Factory should be a step on the way to a Higgs Factory or vice versa as yet remains to be determined. However, decisions on the most effective route for exploring these frontiers are rapidly approaching. Renewed world attention to these opportunities is thus a matter of pressing interest.

Acknowledgments

We thank Patrick Huber and Estia Eichten for extensive and valuable input to this report.
